Multiple linear regression

John Cruz

Grading the professor

Many college courses conclude by giving students the opportunity to evaluate the course and the instructor anonymously. However, the use of these student evaluations as an indicator of course quality and teaching effectiveness is often criticized because these measures may reflect the influence of non-teaching related characteristics, such as the physical appearance of the instructor. The article titled, "Beauty in the classroom: instructors' pulchritude and putative pedagogical productivity" by Hamermesh and Parker found that instructors who are viewed to be better looking receive higher instructional ratings.

Here, you will analyze the data from this study in order to learn what goes into a positive professor evaluation.

Getting Started

Load packages

In this lab, you will explore and visualize the data using the **tidyverse** suite of packages. The data can be found in the companion package for OpenIntro resources, **openintro**.

Let's load the packages.

```
library(tidyverse)
library(openintro)
library(GGally)
```

This is the first time we're using the GGally package. You will be using the ggpairs function from this package later in the lab.

The data

The data were gathered from end of semester student evaluations for a large sample of professors from the University of Texas at Austin. In addition, six students rated the professors' physical appearance. The result is a data frame where each row contains a different course and columns represent variables about the courses and professors. It's called evals.

```

We have observations on 21 different variables, some categorical and some numerical. The meaning of each variable can be found by bringing up the help file:

```
?evals
```

Exploring the data

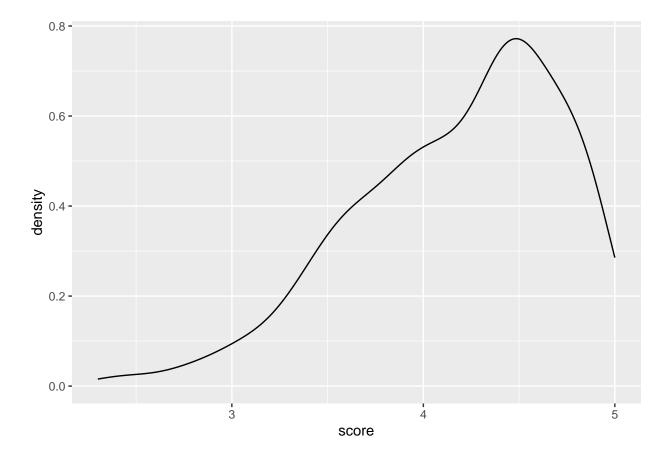

1. Is this an observational study or an experiment? The original research question posed in the paper is whether beauty leads directly to the differences in course evaluations. Given the study design, is it possible to answer this question as it is phrased? If not, rephrase the question.

This is an observational study as it is performed through an evaluation. Given that a professor can alter their perception to others throughout the semester, the question should be, "Does students general opinion of a professor's appearance influence how they score on an evaluation?"

2. Describe the distribution of score. Is the distribution skewed? What does that tell you about how students rate courses? Is this what you expected to see? Why, or why not?

The distribution is left-skewed, and shows that students generally rate courses above average. I expected a right-skewed distribution as I believe people generally take the time to complete evaluations when they have negative experiences.

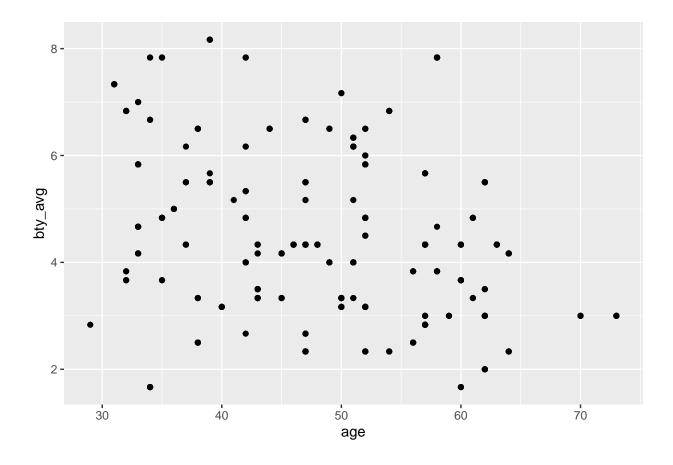

```
evals |>
  ggplot(aes(x = score)) +
  geom_density()
```

3. Excluding score, select two other variables and describe their relationship with each other using an appropriate visualization.

There appears to be a small relationship between age and beauty average. As a professor's age increase, their beauty average range tends to drop and become a narrower range.

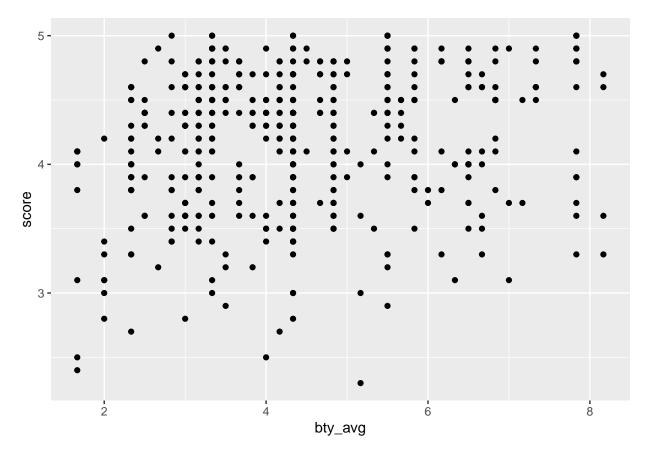

```
evals |>
  ggplot(aes(x = age, y = bty_avg)) +
  geom_point()
```

Simple linear regression

The fundamental phenomenon suggested by the study is that better looking teachers are evaluated more favorably. Let's create a scatterplot to see if this appears to be the case:

```
ggplot(data = evals, aes(x = bty_avg, y = score)) +
  geom_point()
```

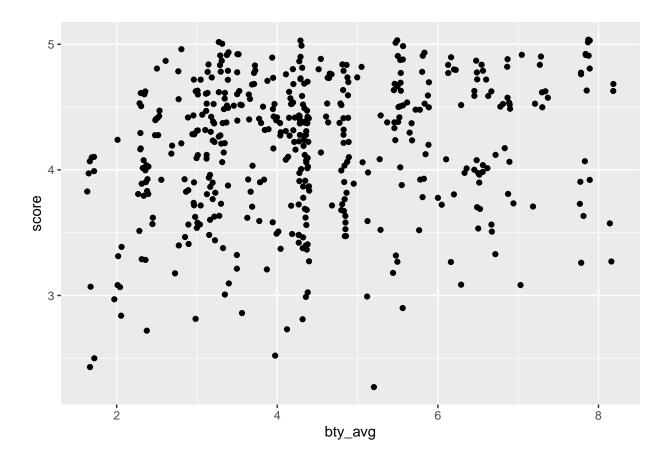

Before you draw conclusions about the trend, compare the number of observations in the data frame with the approximate number of points on the scatterplot. Is anything awry?

Many points appear to be missing from the plot as there should be about 463 plotted observations.

4. Replot the scatterplot, but this time use <code>geom_jitter</code> as your layer. What was misleading about the initial scatterplot?

The initial scatterplot was overfitting the points over each other, where now we can see how the points are not so closely overlapped.

```
ggplot(data = evals, aes(x = bty_avg, y = score)) +
  geom_jitter()
```

5. Let's see if the apparent trend in the plot is something more than natural variation. Fit a linear model called m_bty to predict average professor score by average beauty rating. Write out the equation for the linear model and interpret the slope. Is average beauty score a statistically significant predictor? Does it appear to be a practically significant predictor?

$$\hat{y} = 3.88034 + 0.06664 \times bty_avg$$

Average beauty score appears to be statistically significant. It does not appear to be a practically significant predictor as the overall model's

$$R^2 = 0.03502$$

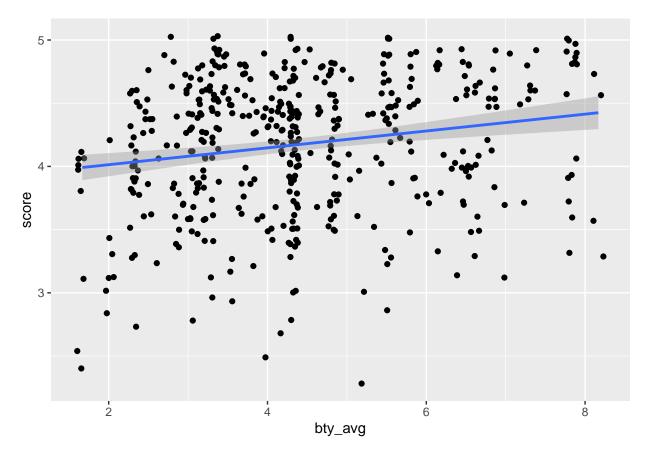

```
m_bty <-
lm(score ~ bty_avg, data = evals)
summary(m_bty)</pre>
```

```
##

                                  Adjusted R-squared: 0.03293
## F-statistic: 16.73 on 1 and 461 DF, p-value: 5.083e-05
```

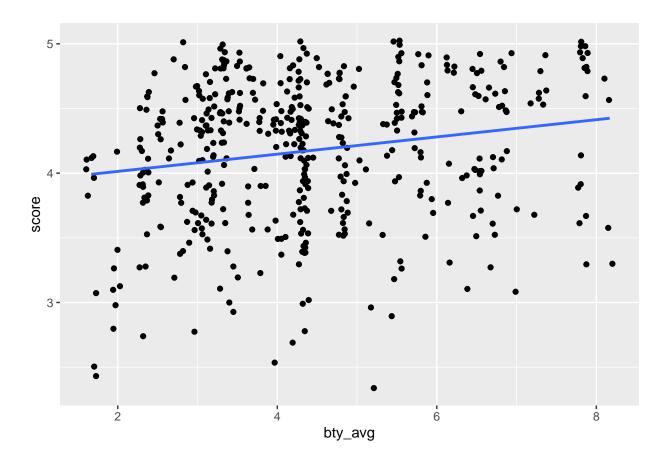

Add the line of the bet fit model to your plot using the following:

```
ggplot(data = evals, aes(x = bty_avg, y = score)) +
geom_jitter() +
geom_smooth(method = "lm")
```

The blue line is the model. The shaded gray area around the line tells you about the variability you might expect in your predictions. To turn that off, use se = FALSE.

```
ggplot(data = evals, aes(x = bty_avg, y = score)) +
  geom_jitter() +
  geom_smooth(method = "lm", se = FALSE)
```

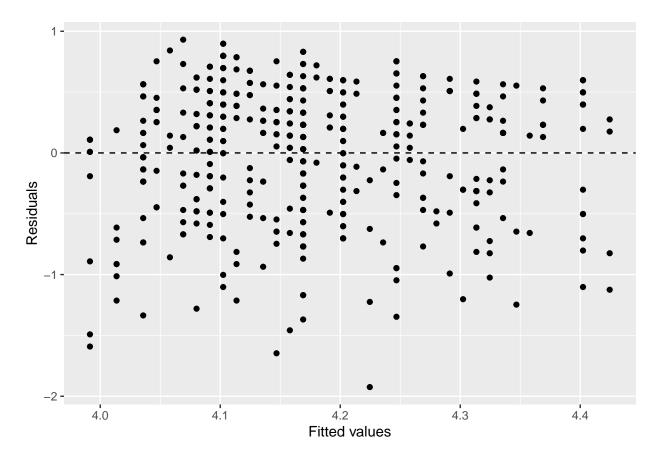

6. Use residual plots to evaluate whether the conditions of least squares regression are reasonable. Provide plots and comments for each one (see the Simple Regression Lab for a reminder of how to make these).

Linearity It passes the linearity test as there does not appear to be any unusual patterns.

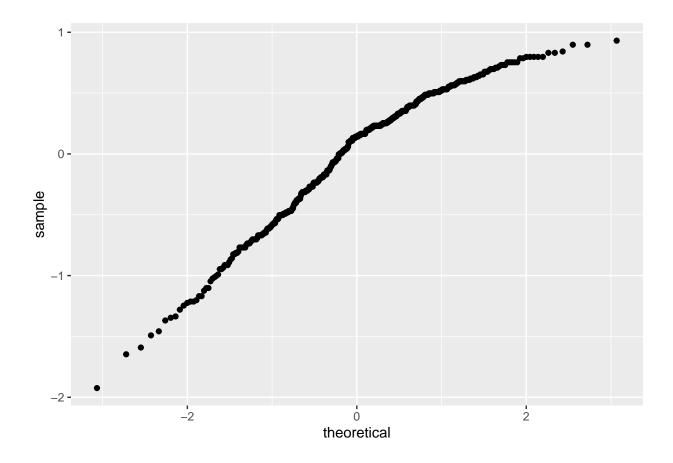

Constant variability The spread around zero does not seem to be distributed equally as there appears to be higher negative residual values, however, overall, there is no unusual pattern

```
ggplot(data = m_bty, aes(x = .fitted, y = .resid)) +
  geom_point() +
  geom_hline(yintercept = 0, linetype = "dashed") +
  xlab("Fitted values") +
  ylab("Residuals")
```

Normality The Q-Q plot shows there is some curvature in the band of residuals, but nothing extreme.

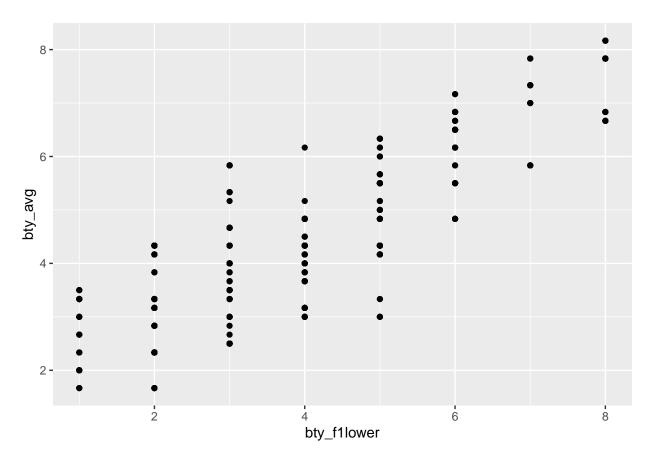

```
ggplot(data = m_bty, aes(sample = .resid)) +
  stat_qq()
```

Multiple linear regression

The data set contains several variables on the beauty score of the professor: individual ratings from each of the six students who were asked to score the physical appearance of the professors and the average of these six scores. Let's take a look at the relationship between one of these scores and the average beauty score.

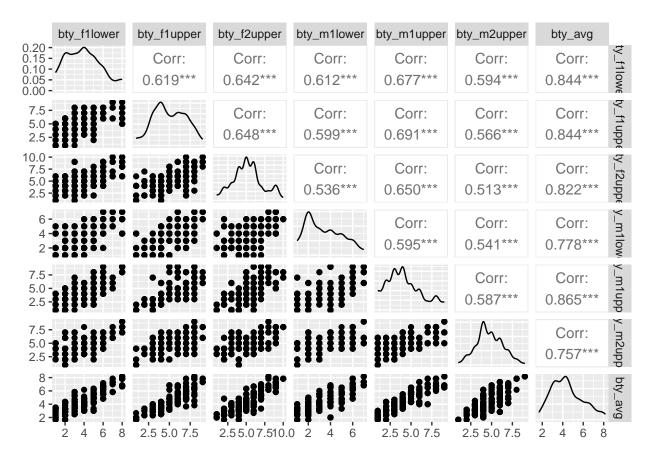

```
ggplot(data = evals, aes(x = bty_f1lower, y = bty_avg)) +
geom_point()
```

```
evals %>%
  summarise(cor(bty_avg, bty_f1lower))
```

As expected, the relationship is quite strong—after all, the average score is calculated using the individual scores. You can actually look at the relationships between all beauty variables (columns 13 through 19) using the following command:

```
evals %>%
  select(contains("bty")) %>%
  ggpairs()
```

These variables are collinear (correlated), and adding more than one of these variables to the model would not add much value to the model. In this application and with these highly-correlated predictors, it is reasonable to use the average beauty score as the single representative of these variables.

In order to see if beauty is still a significant predictor of professor score after you've accounted for the professor's gender, you can add the gender term into the model.

```
m_bty_gen <- lm(score ~ bty_avg + gender, data = evals)
summary(m_bty_gen)</pre>
```

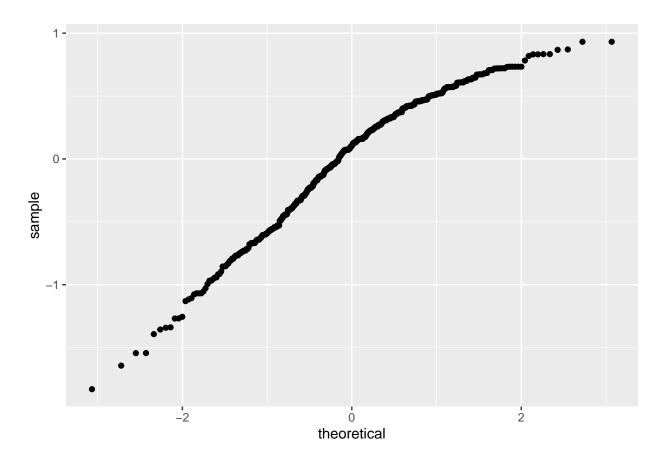

```
##
## Call:
##
  lm(formula = score ~ bty_avg + gender, data = evals)

## Multiple R-squared: 0.05912, Adjusted R-squared: 0.05503
## F-statistic: 14.45 on 2 and 460 DF, p-value: 8.177e-07
```

7. P-values and parameter estimates should only be trusted if the conditions for the regression are reasonable. Verify that the conditions for this model are reasonable using diagnostic plots.

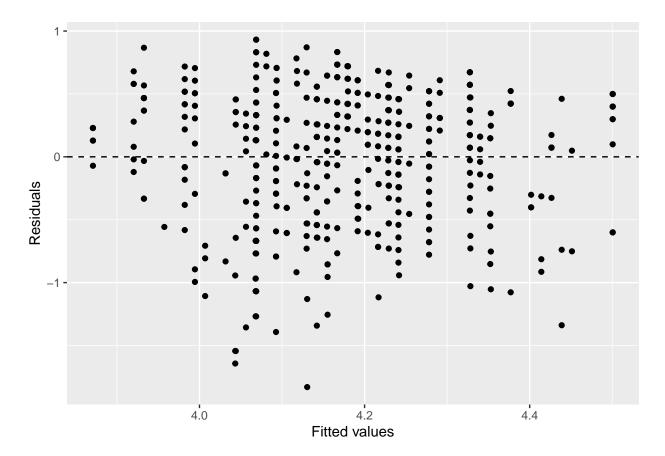

Normality The Q-Q plot shows there is some curvature in the band of residuals, but nothing extreme.

```
ggplot(data = m_bty_gen, aes(sample = .resid)) +
  stat_qq()
```

Constant variability The spread around zero relatively seems to be distributed equally.

```
ggplot(data = m_bty_gen, aes(x = .fitted, y = .resid)) +
  geom_point() +
  geom_hline(yintercept = 0, linetype = "dashed") +
  xlab("Fitted values") +
  ylab("Residuals")
```

Linearity It passes the linearity test as there does not appear to be any unusual patterns.

8. Is bty_avg still a significant predictor of score? Has the addition of gender to the model changed the parameter estimate for bty_avg?

bty_avg is still a significant predictor of score. The addition of gender has changed the parameter estimate for bty_avg to be higher than before. However, it does not appear for bty_avg to be a practically significant predictor as the overall model's

$$R^2 = 0.05503$$

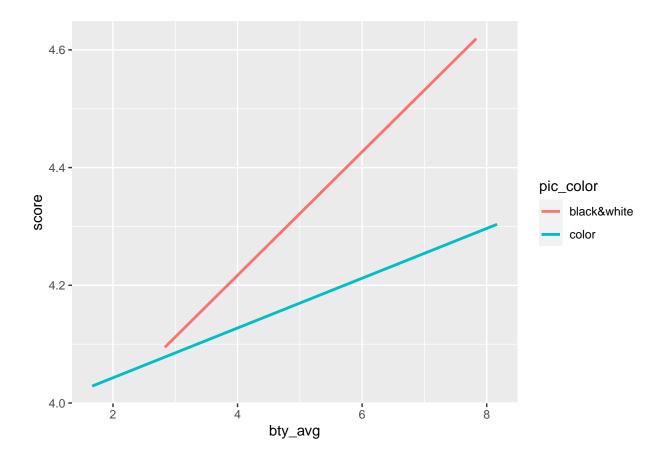

only slightly increased from before.

Note that the estimate for gender is now called gendermale. You'll see this name change whenever you introduce a categorical variable. The reason is that R recodes gender from having the values of male and female to being an indicator variable called gendermale that takes a value of 0 for female professors and a value of 1 for male professors. (Such variables are often referred to as "dummy" variables.)

As a result, for female professors, the parameter estimate is multiplied by zero, leaving the intercept and slope form familiar from simple regression.

$$\widehat{score} = \hat{\beta}_0 + \hat{\beta}_1 \times bty_avg + \hat{\beta}_2 \times (0)$$
$$= \hat{\beta}_0 + \hat{\beta}_1 \times bty_avg$$

```
ggplot(data = evals, aes(x = bty_avg, y = score, color = pic_color)) +
geom_smooth(method = "lm", formula = y ~ x, se = FALSE)
```

9. What is the equation of the line corresponding to those with color pictures? (*Hint:* For those with color pictures, the parameter estimate is multiplied by 1.) For two professors who received the same beauty rating, which color picture tends to have the higher course evaluation score?

```
m_bty_color <- lm(score ~ bty_avg + pic_color, data = evals)
summary(m_bty_color)</pre>
```

```
##
## lm(formula = score ~ bty_avg + pic_color, data = evals)

## Residual standard error: 0.5323 on 460 degrees of freedom
                                    Adjusted R-squared: 0.04213
## Multiple R-squared: 0.04628,
```

```
## F-statistic: 11.16 on 2 and 460 DF, p-value: 1.848e-05
```

Black & White photos tend to receive the higher course evaluation scores.

```
\hat{y} = 4.06318 + 0.05548 \times bty \quad avg - 0.16059 \times pic \quad colorcolor
```

The decision to call the indicator variable gendermale instead of genderfemale has no deeper meaning. R simply codes the category that comes first alphabetically as a 0. (You can change the reference level of a categorical variable, which is the level that is coded as a 0, using therelevel() function. Use ?relevel to learn more.)

10. Create a new model called m_bty_rank with gender removed and rank added in. How does R appear to handle categorical variables that have more than two levels? Note that the rank variable has three levels: teaching, tenure track, tenured.

```
m_bty_rank <- lm(score ~ bty_avg + rank, data = evals)
summary(m_bty_rank)</pre>
```

```
##
## Call:
## lm(formula = score ~ bty_avg + rank, data = evals)
##

```

The reference variable is teaching, and tenure track and tenured are shown as part of the equation.

The interpretation of the coefficients in multiple regression is slightly different from that of simple regression. The estimate for bty_avg reflects how much higher a group of professors is expected to score if they have a beauty rating that is one point higher while holding all other variables constant. In this case, that translates into considering only professors of the same rank with bty_avg scores that are one point apart.

The search for the best model

We will start with a full model that predicts professor score based on rank, gender, ethnicity, language of the university where they got their degree, age, proportion of students that filled out evaluations, class size, course level, number of professors, number of credits, average beauty rating, outfit, and picture color.

11. Which variable would you expect to have the highest p-value in this model? Why? *Hint:* Think about which variable would you expect to not have any association with the professor score.

cls_profs as it should not matter how many teachers are teaching because the score is about the professor themself and not the course itself.

Let's run the model...

```
m_full <- lm(score ~ rank + gender + ethnicity + language + age + cls_perc_eval
            + cls_students + cls_level + cls_profs + cls_credits + bty_avg
            + pic_outfit + pic_color, data = evals)

```

12. Check your suspicions from the previous exercise. Include the model output in your response.

As we look at cls_profs it indeed does have the highest p-value in this model at 0.7786

13. Interpret the coefficient associated with the ethnicity variable.

F-statistic: 7.366 on 14 and 448 DF, p-value: 6.552e-14

If the ethnicity of the professor is "not minority", holding everything else constant, there is an increase on average of 0.1235 to a professor's score, and if they are a minority, this reference variable would be zero.

14. Drop the variable with the highest p-value and re-fit the model. Did the coefficients and significance of the other explanatory variables change? (One of the things that makes multiple regression interesting is that coefficient estimates depend on the other variables that are included in the model.) If not, what does this say about whether or not the dropped variable was collinear with the other explanatory variables?

```
m_full_except_cls_profs <- lm(score ~ rank + gender + ethnicity + language + age + cls_perc_eval
             + cls_students + cls_level + cls_credits + bty_avg

```

In general, the coefficients and significance of the other explanatory variables stayed the same. This means that the variable was not collinear with the other explanatory variables.

15. Using backward-selection and p-value as the selection criterion, determine the best model. You do not need to show all steps in your answer, just the output for the final model. Also, write out the linear model for predicting score based on the final model you settle on.

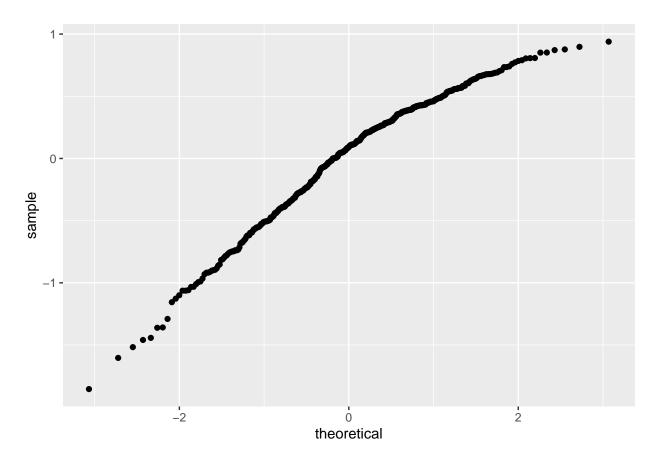

```

```

 $\hat{y} = 3.690771 + 0.201574 \times gendermale + 0.216955 \times ethnicity_notminority - 0.006034 \times age + 0.004719 \times cls_perc_eval + 0.52780 \times cls_perc_eval +$

16. Verify that the conditions for this model are reasonable using diagnostic plots.

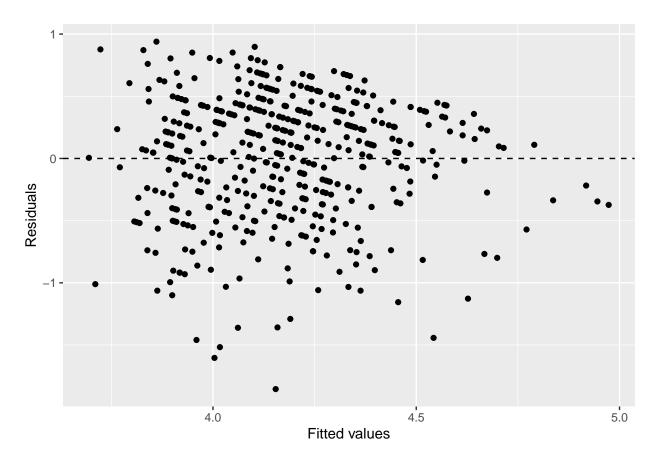

Normality The Q-Q plot shows there is some curvature in the band of residuals, but nothing extreme.

```
ggplot(data = m_backward_sel, aes(sample = .resid)) +
  stat_qq()
```

Constant variability The spread around zero does have some heteroskedacity as it is slightly cone shaped

```
ggplot(data = m_backward_sel, aes(x = .fitted, y = .resid)) +
geom_point() +
geom_hline(yintercept = 0, linetype = "dashed") +
xlab("Fitted values") +
ylab("Residuals")
```

Linearity It generally passes the linearity test but again because of the cone shape of the residuals, some caution needs to be used.

17. The original paper describes how these data were gathered by taking a sample of professors from the University of Texas at Austin and including all courses that they have taught. Considering that each row represents a course, could this new information have an impact on any of the conditions of linear regression?

The course department may provide reasons as to why professor scores may vary such that a heavy calculated math course may be viewed differently than a theory, word based math course.

18. Based on your final model, describe the characteristics of a professor and course at University of Texas at Austin that would be associated with a high evaluation score.

On average, a professor with a high evaluation score would typically be a male, non-minority, that teaches a one credit course and has a black and white picture. Additional factors such as cls_perc_eval, and bty_avg can marginally increase the score, while their age will marginally reduce it.

19. Would you be comfortable generalizing your conclusions to apply to professors generally (at any university)? Why or why not?

I would not be comfortable generalizing these conclusions to professors at any university as the environmental, societal, cultural factors at the University of Texas at Austin may vary significantly compared to other populations.
